

Expressions

var
x : Integer;
y, z : Real;

z := y * (x + 6)

crude approx:

better approx:

Type conversions (implicit)

1. unary conversions —
conversion of a type based
on the type alone (regardless
of content)

In Pascal:

Single → Real

Short → double

String → base type // no auto
conversion

In C, etc.

char → int

short → int

float → double

array of T → pointer to T

unary conversions are applied
first to arguments of any
arith or comparison ops.

2. Binary conversion —
when a binary operator is
applied, first arg is unary
converted by itself, then
each arg is binary converted
based on the type of the
other arg.

convert Integer → Real
if the other arg is Real

Real division op in Pascal
(/) requires two Real
args (may need to convert
both args from Integer to Real).

3. Others, incl. assignment
conversions (r.h.s. of := is converted
to type of l.h.s. before
the assignment).

Real → Single // okay

Real → Integer // error

unary conversions: pointer to void → pointer to T
{ nil and nil } (same my
newest type)

Parameter conversion:
convert actual arg to type
of corresponding formal param of
a proc/fcn.
Same as assignment conversion

Runtime environment:

Use the control stack

Model as a stack machine:

Evaluating an expr at
runtime pushes the value
onto the stack (not result)

Recursively, bottom up:

For constants: push value
onto stack directly

For vars: push (lookup addr)

For unary ops, recursively eval
subexpr (argument) which now
on top of stack. Pop off, apply
operator, then push result back on

For binary ops:

- recursively push value of left arg
- recursively push value of right arg
- pop both off, apply binary op, push result back on.

$x * y + 3$

$x \boxed{5} \text{Int}$
 $y \boxed{7} \text{Int}$

Stack diagram showing the evaluation of $x * y + 3$. The stack initially contains 3, 5, and 7. The value 7 is popped, then 5, and they are multiplied to get 35. Then 3 is added to 35 to get 38.

L-values ("accesses")
 versus
 R-values ("raw values")

R-values: numerical constants
 nil
 arith & comparison operators take R-values as operands and return R-values
 pointer ops & fns are R-values

L-values: variable names
 array access ($a[5]$)
 e.g.

$p^{\wedge}$
 $(*p \text{ in } C)$

$z := y * (x + 6)$

Implicitly fetch the R-value of an L-value (contents at that location) Deref operator

At run time, L-values are always represented on the stack by pointers (regardless of the type)

$z := y * (x + 6)$

1. First push z onto stack (as L-value)
2. Evaluate right-hand side as an R-value
3. Assignment, $baseop()$
4. pop off the value to pop()

Stack diagram showing the execution of $z := y * (x + 6)$. The stack contains 3, 14, and 3. The value 3 is popped, then 14, and they are multiplied to get 42. Then 42 is assigned to z , and 3 is popped.

When building syntax tree must implicitly convert L-values to R-values when expected (Deref)

$z := y * (x + 6)$

Final version of r.v.s.

Syntax tree diagram for $z := y * (x + 6)$. The root is an assignment node with L-value z and R-value $y * (x + 6)$. The R-value node has children y and $x + 6$. The $x + 6$ node has children x and 6 . All L-values are marked with "Deref".

$\Delta: R \rightarrow L$
 $t = r_1 \dots r_n: R \times R \rightarrow R$
 $\&: L \rightarrow R$

$P^{\wedge} := Q^{\wedge}$ {P, Q both pointers to Integer}

Diagram showing the evaluation of $P^{\wedge} := Q^{\wedge}$. The stack contains 5, 10, and 15. The value 15 is popped, then 10, and they are compared to get 0. Then 0 is assigned to P , and 5 is popped.
