Abstract. An infinite binary sequence $x$ is defined to be
1. strongly useful if there is a recursive time bound within which every
recursive sequence is Turing reducible to $x$; and
2. weakly useful if there is a recursive time bound within which all the
sequences in a non-measure 0 subset of the set of recursive sequences
are Turing reducible to $x$.

Juedes, Lathrop, and Lutz (1994) proved that every weakly useful se-
quence is strongly deep in the sense of Bennett (1988) and asked whether
there are sequences that are weakly useful but not strongly useful.
The present paper answers this question affirmatively. The proof is a
direct construction that combines the recent martingale diagonaliza-
technique of Lutz (1994) with a new technique, namely, the construc-
tion of a sequence that is “recursively deep” with respect to an arbi-
trary, given uniform reducibility. The abundance of such recursively
deep sequences is also proven and used to show that every weakly useful
sequence is recursively deep with respect to every uniform reducibility.

1 Introduction

It is a truism that the usefulness of a data object does not vary directly with
its information content. For example, consider two infinite binary strings, $\chi_K$,
the characteristic sequence of the halting problem (whose $n$th bit is 1 if and
only if the $n$th Turing machine halts on input $n$), and $z$, a sequence that is
algorithmically random in the sense of Martin-Löf [10]. The following facts are
well-known.

1. The first $n$ bits of $\chi_K$ can be specified using only $O(\log n)$ bits of informa-
tion, namely, the number of 1’s in the first $n$ bits of $\chi_K$ [2].

9157382, with matching funds from Rockwell International, Microwave Systems
Corporation, and Amoco.

*** Work supported by the EC through the Esprit BRA Program (project 7141, AL-
COM II) and through the HCM Program (project CHRX-CT93-0415, COLORET
Network).
2. The first $n$ bits of $z$ cannot be specified using significantly fewer than $n$ bits of information [10].

3. Oracle access to $\chi_K$ would enable one to decide any recursive sequence in polynomial time (i.e., decide the $n$th bit of the sequence in time polynomial in the length of the binary representation of $n$) [11].

4. Even with oracle access to $z$, most recursive sequences cannot be computed in polynomial time. (This appears to be folklore, known at least since [3].)

Facts (i) and (ii) tell us that $\chi_K$ contains far less information than $z$. In contrast, facts (iii) and (iv) tell us that $\chi_K$ is computationally much more useful than $z$. That is, the information in $\chi_K$ is “more usefully organized” than that in $z$.

Bennett [3] introduced the notion of computational depth (also called “logical depth”) in order to quantify the degree to which the information in an object has been organized. In particular, for infinite binary sequences, Bennett defined two “levels” of depth, strong depth and weak depth, and argued that the above situation arises from the fact that $\chi_K$ is strongly deep, while $z$ is not even weakly deep. (The present paper is motivated by the study of computational depth, but does not directly use strong or weak depth, so definitions are omitted here. The interested reader is referred to [3], [7], or [6] for details, and for related aspects of algorithmic information theory.)

Investigating this matter further, Juedes, Lathrop, and Lutz [6] considered two “levels of usefulness” for infinite binary sequences. Specifically, let $\{0, 1\}^\infty$ be the set of all infinite binary sequences, let $\text{REC}$ be the set of all recursive elements of $\{0, 1\}^\infty$, and, for $x \in \{0, 1\}^\infty$ and $t : \mathbb{N} \to \mathbb{N}$, let $\text{DTIME}^x(t)$ be the set of all $y \in \{0, 1\}^\infty$ for which there exists an oracle Turing machine $M$ that, on input $n \in \mathbb{N}$ with oracle $x$, computes $y[n]$, the $n$th bit of $y$, in at most $t(\ell)$ steps, where $\ell$ is the number of bits in the binary representation of $n$. Then a sequence $x \in \{0, 1\}^\infty$ is defined to be strongly useful if there is a recursive time bound $t : \mathbb{N} \to \mathbb{N}$ such that $\text{DTIME}^x(t)$ contains all of $\text{REC}$. A sequence $x \in \{0, 1\}^\infty$ is defined to be weakly useful if there is a recursive time bound $t : \mathbb{N} \to \mathbb{N}$ such that $\text{DTIME}^x(t)$ contains a non-measure 0 subset of $\text{REC}$, in the sense of resource-bounded measure [9]. That is, $x$ is weakly useful if access to $x$ enables one to decide a nonnegligible set of recursive sequences within some fixed recursive time bound. No recursive or algorithmically random sequence can be weakly useful. It is evident that $\chi_K$ is strongly useful, and that every strongly useful sequence is weakly useful.

Juedes, Lathrop, and Lutz [6] generalized Bennett’s result that $\chi_K$ is strongly deep by proving that every weakly useful sequence is strongly deep. This confirmed Bennett’s intuitive arguments by establishing a definite relationship between computational depth and computational usefulness. It also substantially extended Bennett’s result on $\chi_K$ by implying (in combination with known results of recursion theory [10, 13, 4, 5]) that all high Turing degrees and some low Turing degrees contain strongly deep sequences.

Notwithstanding this progress, Juedes, Lathrop, and Lutz [6] left a critical question open: Do there exist weakly useful sequences that are not strongly useful? The main result of the present paper, proved in Section 4, answers this
question affirmatively. This establishes the existence of strongly deep sequences that are not strongly useful. More importantly, it indicates a need for further investigation of the class of weakly useful sequences.

The proof of our main result is a direct construction that combines the martingale diagonalization technique recently introduced by Lutz [8] with a new technique, namely, the construction of a sequence that is recursively F-deep, where F is an arbitrary uniform reducibility. This notion of uniform recursive depth, defined and investigated in Section 3, is closely related to Bennett’s notion of weak depth.

In addition to using specific constructions of recursively F-deep sequences, we prove that, for each uniform reducibility F, almost every sequence in REC is recursively F-deep. This implies that every weakly useful sequence is, for every uniform reducibility F, recursively F-deep.

2 Preliminaries

We use \( \mathbb{N} \) to denote the set of natural numbers (including 0), and we use \( \mathbb{Q} \) to denote the set of rational numbers. We write \([\varphi]\) for the Boolean value of a condition \( \varphi \), i.e.,

\[
[\varphi] = \begin{cases} 1 & \text{if } \varphi \text{ is true} \\ 0 & \text{else} \end{cases}
\]

Throughout this paper, we identify each set \( A \subseteq \mathbb{N} \) with its characteristic sequence \( \chi_A \in \{0,1\}^\mathbb{N} \), whose \( n \)th bit is \( \chi_A[n] = \lfloor n \in A \rfloor \). For any \( x, y \in \{0,1\}^* \cup \{0,1\}^\mathbb{N} \), we write \( x \sqsubseteq y \) to mean that \( x \) is a prefix of \( y \), and if in addition, \( x \neq y \), we may write \( x \sqsubset y \).

We fix a recursive bijection \( \langle \cdot, \cdot \rangle: \mathbb{N} \times \mathbb{N} \to \mathbb{N} \), monotone in both arguments, such that \( i \leq \langle i, j \rangle \) and \( j \leq \langle i, j \rangle \) for all \( i, j \in \mathbb{N} \).

In the proof of Theorem 12, we will deal extensively with partial characteristic functions, i.e., functions with domain a subset of \( \mathbb{N} \) and with range \( \{0,1\} \). We will identify binary strings with characteristic functions whose domains are finite initial segments of \( \mathbb{N} \). If \( \sigma \) and \( \tau \) are partial characteristic functions, we let \( \text{dom}(\sigma) \) denote the domain of \( \sigma \), and say that \( \sigma \) and \( \tau \) are compatible if they agree on all elements in \( \text{dom}(\sigma) \cap \text{dom}(\tau) \). We say that \( \sigma \) is extended by \( \tau \) (\( \sigma \sqsubseteq \tau \)) if \( \sigma \) and \( \tau \) are compatible and \( \text{dom}(\sigma) \subseteq \text{dom}(\tau) \) (if in addition \( \sigma \neq \tau \), we write \( \sigma \sqsubset \tau \)). If \( \sigma \) and \( \tau \) are compatible, we let \( \sigma \cup \tau \) be their smallest common extension.

We will often think of \( \mathbb{N} \) being split up into columns \( 0, 1, 2, \ldots \) where the \( i \)th column is \( \{\langle i, j \rangle \mid j \in \mathbb{N} \} \). If \( A \subseteq \mathbb{N} \), then the \( i \)th strand of \( A \) is defined as \( A_i = \{ x \mid \langle i, x \rangle \in A \} \). If \( \sigma \) is a partial characteristic function and \( n \in \mathbb{N} \), then \( \sigma \upharpoonright n \) denotes \( \sigma \) restricted to the domain \( \{0, \ldots, n-1\} \), and \( \sigma \upharpoonright i, < n \) denotes the unique partial characteristic function \( \tau \) such that for all \( x \),

\[
\tau(x) = \begin{cases} \sigma(\langle i, x \rangle) & \text{if } x < n \text{ and } \sigma(\langle i, x \rangle) \text{ is defined,} \\ \text{undefined otherwise.} & \end{cases}
\]

That is, \( \sigma \upharpoonright i, < n \) results from “excising” the first \( n \) bits of \( \sigma \) from the \( i \)th column. Inversely, if \( w \) is a binary string, then \( \{i\} \times w \) denotes the unique partial
characteristic function \( \tau \) such that \( \tau((i, x)) = w(x) \) for all \( x < |w| \), and is undefined on all other arguments. That is, \( \{i\} \times w \) is \( w \) “translated” over to the \( i \)th column. Of particular importance will be the finite characteristic function defined for an arbitrary \( C \subseteq \mathbb{N} \) and \( k, y \in \mathbb{N} \) as

\[
\xi(k, y) = \bigcup_{k' < k} \{k'\} \times C[k', < y].
\]

In other words, \( \xi(k, y) \) is \( \chi_C \) restricted to the “rectangle” of width \( k \) and height \( y \), with a corner at the origin.

Weakly useful sequences are defined (in Section 1) in terms of recursive measure, a special case of the resource-bounded measure developed by Lutz [9]. We very briefly sketch the elements of this theory, referring the reader to [9, 8] for motivation, details, and intuition.

**Definition 1.** A martingale is a function \( d: \{0, 1\}^* \to [0, \infty) \) such that, for all \( w \in \{0, 1\}^* \),

\[
d(w) = \frac{d(w0) + d(w1)}{2}.
\]

**Definition 2.** A martingale \( d \) is recursive if there is a total recursive function \( \hat{d}: \mathbb{N} \times \{0, 1\}^* \to \mathbb{Q} \) such that, for all \( r \in \mathbb{N} \) and \( w \in \{0, 1\}^* \),

\[
\left| \hat{d}(r, w) - d(w) \right| \leq 2^{-r}.
\]

**Definition 3.** A martingale \( d \) succeeds on a sequence \( x \in \{0, 1\}^\infty \) if

\[
\limsup_{n \to \infty} d(x[0\ldots n - 1]) = \infty,
\]

where \( x[0\ldots n - 1] \) is the \( n \)-bit prefix of \( x \). The success set of a martingale \( d \) is

\[
S^\infty[d] = \{x \in \{0, 1\}^\infty \mid \text{d succeeds on } x\}.
\]

**Definition 4.** Let \( X \subseteq \{0, 1\}^\infty \).

1. \( X \) has recursive measure \( \theta \), and we write \( \mu_{rec}(X) = 0 \), if there is a recursive martingale \( d \) such that \( X \subseteq S^\infty[d] \).
2. \( X \) has recursive measure \( I \), and we write \( \mu_{rec}(X) = 1 \), if \( \mu_{rec}(X^c) = 0 \), where \( X^c = \{0, 1\}^\infty - X \) is the complement of \( X \).
3. \( X \) has measure \( \theta \) in \( \text{REC} \), and we write \( \mu(X \mid \text{REC}) = 0 \), if \( \mu_{rec}(X \cap \text{REC}) = 0 \).
4. \( X \) has measure \( I \) in \( \text{REC} \), and we write \( \mu(X \mid \text{REC}) = 1 \), if \( \mu(X^c \mid \text{REC}) = 0 \). In this case, we say that \( X \) contains almost every element of \( \text{REC} \).
3 Uniform Recursive Depth

In this section we prove that, for every uniform reducibility $F$, almost every recursive subset of $\mathbb{N}$ has a certain "depth" property with respect to $F$. This depth property is used in the proof of our main result in Section 4. It is also of independent interest because it is closely related to Bennett’s notion of weak depth [3].

We first make our terminology precise. As in [12], we define a truth-table condition (briefly, a tt-condition) to be an ordered pair $\tau = ((n_1, \ldots, n_k), g)$, where $k, n_1, \ldots, n_k \in \mathbb{N}$ and $g : \{0,1\}^k \to \{0,1\}$. We write TTC for the class of all tt-conditions. The tt-value of a set $B \subseteq \mathbb{N}$ under a tt-condition $\tau = ((n_1, \ldots, n_k), g)$ is the bit

$$\tau^B = g([n_1 \in B] \cdots [n_k \in B]).$$

A truth-table reduction (briefly, a tt-reduction) is a total recursive function $F: \mathbb{N} \to \text{TTC}$. If $F$ is a tt-reduction and $F(x) = ((n_1, \ldots, n_k), g)$, then we call $n_1, \ldots, n_k$ the queries made by $F$ on input $x$. A truth-table reduction $F$ naturally induces a function $\hat{F}: \mathcal{P}(\mathbb{N}) \to \mathcal{P}(\mathbb{N})$ defined by

$$\hat{F}(B) = \{ n \in \mathbb{N} \mid F(n)^B = 1 \}.$$

In general, we identify a truth-table reduction $F$ with the induced function $\hat{F}$, writing $F$ for either function and relying on context to avoid confusion.

The following terminology is convenient for our purposes.

**Definition 5.** A uniform reducibility is a total recursive function $F : \mathbb{N} \times \mathbb{N} \to \text{TTC}$. If $F$ is a uniform reducibility, then we use the notation $F_k(n) = F(k,n)$ for all $k,n \in \mathbb{N}$. We thus regard a uniform reducibility as a recursive sequence $F_0, F_1, F_2, \ldots$ of tt-reductions.

**Definition 6.** If $F$ is a uniform reducibility and $A, B \subseteq \mathbb{N}$, then we say that $A$ is $F$-reducible to $B$, and we write $A \leq_F B$, if there exists $k \in \mathbb{N}$ such that $A = F_k(B)$.

**Example 1.** Fix a recursive time bound, i.e., a total recursive function $t: \mathbb{N} \to \mathbb{N}$. It is routine to construct a uniform reducibility $F$ such that, for all $A, B \subseteq \mathbb{N},$

$$A \leq_F B \iff A \in \text{DTIME}^B(t).$$

**Definition 7.** Let $F$ be a uniform reducibility. The upper $F$-span of a set $A \subseteq \mathbb{N}$ is the set

$$F^{-1}(A) = \{ B \subseteq \mathbb{N} \mid A \leq_F B \}.$$

**Definition 8.** Let $F$ be a uniform reducibility. A set $A \subseteq \mathbb{N}$ is recursively $F$-deep if $\mu_{\text{rec}}(F^{-1}(A)) = 0$. 
Bennett \cite{Bennett} defines a set \( A \subseteq \mathbb{N} \) to be \emph{weakly deep} if \( A \) is not tt-reducible to any algorithmically random set \( B \). The above definition is similar in spirit, but it (i) replaces “tt-reducible” with “\( F \)-reducible,” and (ii) replaces “any algorithmically random set \( B \)” with “any set \( B \) outside a set of recursive measure 0.”

**Definition 9.** A set \( A \subseteq \mathbb{N} \) is \emph{recursively weakly deep} if, for every uniform reducibility \( F \), \( A \) is recursively \( F \)-deep.

It is easy to see that every recursively weakly deep set is weakly deep.

We now prove the main result of this section. Recalling our identification of subsets of \( \mathbb{N} \) with their characteristic sequences, we state this result in terms of sequences but, for convenience, prove it in terms of sets.

**Theorem 10.** If \( F \) is a uniform reducibility, then almost every sequence in \( \text{REC} \) is recursively \( F \)-deep.

**Proof sketch** Assume the hypothesis. For each \( k, n \in \mathbb{N} \) and \( A \subseteq \mathbb{N} \), define the set

\[
\mathcal{E}^A_{k,n} = \{ B \subseteq \mathbb{N} \mid (\forall 0 \leq m < n)[m \in A] \Rightarrow [m \in F_k(B)] \}.
\]

This is the set of all \( B \) such that \( F_k(B) \) agrees with \( A \) on \( 0,1,\ldots,n-1 \). In particular,

\[
F^{-1}(A) = \bigcup_{k=0}^{\infty} \bigcap_{n=0}^{\infty} \mathcal{E}^A_{k,n}.
\]

We regard \( \mathcal{E}^A_{k,n} \) as an event in the sample space \( \mathcal{P}(\mathbb{N}) \) with the uniform distribution. Thus we write \( \Pr(\mathcal{E}^A_{k,n}) \) for the probability that \( B \in \mathcal{E}^A_{k,n} \), where the set \( B \subseteq \mathbb{N} \) is chosen probabilistically according to a random experiment in which an independent toss of a fair coin is used to decide membership of each natural number in \( B \).

For each \( A \subseteq \mathbb{N} \), define a function \( d^A : \{0,1\}^* \to [0,\infty) \) by

\[
d^A(w) = \sum_{k=0}^{\infty} \sum_{n=0}^{\infty} 2^{-k+n} d_{k,n}^A(w),
\]

where, for all \( k, n \in \mathbb{N} \) and \( w \in \{0,1\}^* \),

\[
d_{k,n}^A(w) = \begin{cases} 2^{\left|w\right|} \Pr(C_w \mid \mathcal{E}^A_{k,n}) & \text{if } \Pr(\mathcal{E}^A_{k,n}) > 0, \\ 1 & \text{if } \Pr(\mathcal{E}^A_{k,n}) = 0, \end{cases}
\]

where \( C_w = \{ A \subseteq \mathbb{N} \mid w \subseteq \chi_A \} \). It is routine to check that each \( d^A \) is a martingale that is recursive in \( A \).

For each \( k, n \in \mathbb{N} \) and \( A \subseteq \mathbb{N} \), let

\[
N_A(k,n) = \left\{ m \mid 0 \leq m < n \text{ and } \Pr(\mathcal{E}^A_{k,m+1}) \leq \frac{1}{2} \Pr(\mathcal{E}^A_{k,m}) \right\},
\]
and let
\[ X = \left\{ A \subseteq \mathbb{N} \mid (\forall k \in \mathbb{N})(\forall n \in \mathbb{N})N_A(k, n) > \frac{n}{4} \right\}, \]
where the quantifier \((\forall n \in \mathbb{N})\) means “for all but finitely many \(n \in \mathbb{N}\).”

We use the following four claims (proofs are omitted).

**Claim 1** For all \(k, n \in \mathbb{N}\) and \(A \subseteq \mathbb{N}\),
\[ \Pr(\mathcal{E}^A_{k, n}) \leq 2^{-N_A(k, n)}. \]

**Claim 2** For all \(k, n \in \mathbb{N}\) and \(A, B \subseteq \mathbb{N}\) satisfying \(A = F_k(B)\),
\[ \liminf_{\ell \to \infty} d^A_{k, n}(\chi_B[0 \ldots \ell - 1]) \geq 2^{N_A(k, n)}. \]

**Claim 3** For all \(A \in X\), \(F^{-1}(A) \subseteq S^\infty[d^A]\).

**Claim 4** \(\mu_{\text{rec}}(X) = 1\).

Let
\[ D = \{ A \subseteq \mathbb{N} \mid A \text{ is recursively } F\text{-deep} \}. \]

By Claim 3 and the fact that \(d^A\) is recursive in \(A\), we must have \(X \cap \text{REC} \subseteq D\).
It follows that \(D^c \cap \text{REC} \subseteq X^c\). Claim 4 tells us that \(\mu_{\text{rec}}(X^c) = 0\), and hence
\[ \mu(D^c \mid \text{REC}) = \mu_{\text{rec}}(D^c \cap \text{REC}) = 0, \]
since any subset of a rec-measure 0 set has rec-measure 0. We thus get \(\mu(D \mid \text{REC}) = 1\), which proves the theorem. \(\square\)  **Theorem 10**

**Theorem 11.** Every weakly useful sequence is recursively weakly deep.

**Proof.** Assume that \(A\) is weakly useful and fix a uniform reducibility \(F\). It suffices to show that \(\mu_{\text{rec}}(F^{-1}(A)) = 0\).

Fix a recursive time bound \(t : \mathbb{N} \to \mathbb{N}\) such that \(\mu(\text{DTIME}^A(t) \mid \text{REC}) \neq 0\). Then there is a uniform reducibility \(\bar{F}\) such that, for all \(B, C, D \subseteq \mathbb{N}\),
\[ [B \in \text{DTIME}^C(t) \text{ and } C \leq_F D] \implies B \leq_F D. \]

Let \(X\) be the set of all sets that are recursively \(\bar{F}\)-deep. By Theorem 10, \(\mu(X \mid \text{REC}) = 1\), so there is a set \(B \in X \cap \text{DTIME}^A(t) \cap \text{REC}\). Now \(\mu_{\text{rec}}(\bar{F}^{-1}(B)) = 0\) (because \(B \in X\)) and \(F^{-1}(A) \subseteq \bar{F}^{-1}(B)\) (because \(B \in \text{DTIME}^A(t)\)), so \(\mu_{\text{rec}}(F^{-1}(A)) = 0\). \(\square\)
4 Main Result

In this section, we prove the existence of weakly useful sequences that are not strongly useful. Our construction uses recursively $F$-deep sets (for an infinite, nonuniform collection of uniform reducibilities $F$), but those sets are constructed in a canonical way.

**Theorem 12.** There is a sequence that is weakly useful but not strongly useful.

We include a sketch of the proof of Theorem 12. The proof uses the next proposition, which is of independent interest.

**Proposition 13.** If $F$ is a uniform reducibility, then there is a canonical recursive, recursively $F$-deep set, i.e., a set $A$ such that

$$
\mu_{\text{rec}}(\{ B \mid (\exists i) A = F_i(B) \}) = 0,
$$

and such that for all $x, i \in \mathbb{N}$, $\Pr_C[F_i(C)[i, < x] = A[i, < x]] \leq 2^{-x}$.

We call $A$ above the canonical recursively $F$-deep set.

**Proof sketch of Theorem 12** Our proof is an adaptation of the martingale diagonalization method introduced by Lutz in [8]. We will define $H$ one strand at a time to satisfy the following conditions, where $H_0, H_1, H_2, \ldots$ are the strands of $H$:

1. Each strand $H_k$ is recursive (although $H$ itself cannot be recursive).
2. If $d$ is any recursive martingale, then there is some $k$ such that $d$ fails on $H_k$.
3. For every recursive time bound $t$, there is a recursive set $A$ such that $A \not\in \text{DTIME}^H(t)$.

These three conditions suffice for our purposes. By Condition 1, the set $J = \{ H_0, H_1, H_2, \ldots \} \subseteq \text{REC}$, and by Condition 2, no recursive martingale can succeed on all its elements. Thus $\mu_{\text{rec}}(J) \neq 0$, which makes $H$ weakly useful, since $J \subseteq \text{DTIME}^H(\text{linear})$. Condition 3 ensures that $H$ is not strongly useful.

Fix an arbitrary enumeration $\{ t_k \}_{k \in \mathbb{N}}$ of all recursive time bounds, and an enumeration $\{ d_k \}_{k \in \mathbb{N}}$ of all recursive martingales. These enumerations need not be uniform in any sense, since at present we are not trying to control the complexity of $H$. We will define (in order) a number of different objects for each $k$:

- a uniform reducibility $F^k$ corresponding to $t_k$.
- a recursive $A^k$ such that $A^k \not\in \text{DTIME}^H(t_k)$ ($A^k$ will be the canonical recursively $F^k$-deep set (cf. Proposition 13),
- a partial characteristic function $\alpha_k$ of finite domain, compatible with all the previous strands of $H$ (ultimately, $\alpha_k \subseteq H$ for all $k$),
- martingales $d_{i,j}^{k,q}$ (uniformly recursive over $j$ and $q$) for all $i,j,q \in \mathbb{N}$ with $i \leq k$, which, taken together, witness that each $A^i$ is recursively $F^i$-deep, and

the strand $H_k$ itself, which is designed to make the martingale

$$d_k' = \tilde{d}_k + \sum_{i=0}^{k} \sum_{j=0}^{\infty} \sum_{q=0}^{\infty} d_{i, j; q} \cdot 2^{-q-j}$$

fail on $H_k$, thus satisfying Condition 2 above. $H_k$ will also participate in a fixed finite number of diagonalizations against tt-reductions from the $A^i$ to $H$ for $i \leq k$.

Fix $k \in \mathbb{N}$, and assume that all the above objects have been defined for all $k' < k$ (define $\alpha_{-1} = \lambda$). Also assume that for each $k' < k$ we have at our disposal programs to compute (uniformly over $j$ and $q$) $F_{j}^{k'}$, $A^{k'}$, $H_{k'}$, and $d_{j, q}^{k'}$ for all $i \leq k'$. Let $\{M_{j, k}\}_{k \in \mathbb{N}}$ be a recursive enumeration of all oracle Turing machines running in time $t_k$, and for all $j$ let $M_{j, k}$ be the same as $M_{j, k}$ except that when $M_{j, k}$ makes a query of the form $\langle x, y \rangle$ for $x < k$, $M_{j, k}'$ instead simulates the answer by computing $H_x(y)$ directly. We let $F_{j}^{k}$ be the tt-reduction corresponding to $M_{j, k}'$. Note that on any input, $F_{j}^{k}$ only makes queries of the form $\langle x, y \rangle$ for $x \geq k$.

We define $A^{k}$ to be the canonical recursively $F^{k}$-deep set constructed in the proof of Proposition 13, therefore,

**Fact 1** For all $j, k, x \in \mathbb{N}$, $\Pr_C[F_{j}^{k}(C) \mid j, < x] = A^{k} \mid j, < x] \leq 2^{-x}$.

Let $H_{<k}$ denote the partial characteristic function that agrees with $H$ on all $\langle x, y \rangle$ with $x < k$, and is undefined otherwise. Given $\alpha_{k-1}$, which is compatible with $H_{<k}$, we define $\alpha_k$ as follows: let $\langle i, j \rangle = k$. If there is a set $C \supseteq H_{<k} \cup \alpha_{k-1}$ such that $A^i \neq F_{j}^{k}(C)$, then we diagonalize against $F_{j}^{k}$ by letting $\alpha_k$ be the least finite characteristic function extending $\alpha_{k-1}$ that preserves such a miscomputation, i.e., for some $C$ and $x$ such that $A^i(x) \neq F_{j}^{k}(x) \upharpoonright C$, $\alpha_k$ will agree with $C$ on all queries made by $F_{j}^{k}$ on input $x$. If no such $C$ exists, let $\alpha_k = \alpha_{k-1}$.

Now fix any $i$ and $j$ with $i \leq k$. We would like to define a martingale that succeeds on all $B$ such that $A^i = F_{j}^{k}(B)$. We cannot do this directly, because any given tt-reduction $F_{j}^{k}$ from $A^i$ to $H$ might make queries on many different columns at once, and our martingales can only act on one column at a time. Instead, for any $q \in \mathbb{N}$ large enough, the martingales $d_{j, q}^{i, j}$ for all $k' \geq i$ will act together to “succeed as a group” on all sets to which $A^i$ reduces via $F_{j}^{k}$.

The martingale $d_{j, q}^{i, j}$ will be split up into infinitely many martingales

$$d_{j, q}^{i, j} = \sum_{t=1}^{\infty} d_{j, q}^{i, j; t}$$

where each martingale $d_{j, q}^{i, j; t}$ bets a finite number of times. Fix $i$ and $j$. For any $m \in \mathbb{N}$, let $y_m$ be least such that $v < y_m$ for all queries $\langle u, v \rangle$ made by $F_{j}^{k}$ on inputs $\langle j, x \rangle$ for all $x < m$. For any $C \subseteq \mathbb{N}$, let $E^{C}(m)$ be the event that
$F_j^i(C)_{j < m} = A^i[j, < m]$, i.e., that $F_j^i(C)$ and $A^i$ agree on the first $m$ elements of the $j$th column. For all $w \in \{0, 1\}^*$, we define

$$d_{k;j;\ell}^i(w) = 2^{|w|} - \ell,$$

$$\Pr C \left[ \xi^H(\langle k, y_{\ell}\rangle) \cup (\{k\} \times w) \cap C \mid \xi^H(\langle k, y_{\ell}\rangle) \cap C & E^C(q_{\ell}) \right]$$

if $\Pr C \left[ \xi^H(\langle k, y_{\ell}\rangle) \cap C & E^C(q_{\ell}) \right] > 0$. Otherwise, for all $w$ define $d_{k;j;\ell}^i(w) = 2^{-\ell}$.

We now define $H_k$. For any $y$, we assume that $H_k[< y]$ has already been defined, and we set $w = H_k[< y]$. Let

$$H_k(y) = \begin{cases} \alpha_k(\langle k, y \rangle) & \text{if } \alpha_k(\langle k, y \rangle) \text{ is defined,} \\ 0 & \text{if } \alpha_k(\langle k, y \rangle) \text{ is undefined and } d_k^i(w0) \leq d_k^i(w1), \\ 1 & \text{if } \alpha_k(\langle k, y \rangle) \text{ is undefined and } d_k^i(w0) > d_k^i(w1). \end{cases}$$

**Remark.** Actually, we cannot do this exactly as stated. A recursive martingale such as $d_k^i$ cannot in general be computed exactly, but is only approximated. What we are really comparing are not $d_k^i(w0)$ and $d_k^i(w1)$, but rather their $y$th approximations, which are computable. Since these approximations are guaranteed to be within $2^{-y}$ of the actual values, and our sole aim is to make $d_k^i$ fail on $H_k$, it suffices for our purposes to consider only the approximations when doing the comparisons above. The same trick is used in [8].

$H_k$ is evidently recursive (given the last remark), and for cofinitely many $y$, $H_k(y)$ is chosen so that $d_k^i(H_k[< (y + 1)]) \leq d_k^i(H_k[< y]) + 2^{-y}$, the $2^{-y}$ owing to the error in the approximation of $d_k^i$. Thus $d_k^i$ fails on $H_k$, from which we obtain

**Fact 2** The martingales $d_k^i$ and $d_{k;j;\ell}^i$ for all $i \leq k$, $j$, and $q$ all fail on $H_k$.

Thus Conditions 1 and 2 are satisfied. Each $H_k$ also preserves the diagonalization commitments made by the $\alpha_k$ for all $k' \leq k$, so the following is easily checked:

**Fact 3** $\alpha_0 \subseteq \alpha_1 \subseteq \alpha_2 \subseteq \cdots \subseteq H$.

To verify Condition 3, we show that $A^i \neq F_j^i(H)$ for all $i$ and $j$. Suppose $A^i = F_j^i(H)$ for some $i$ and $j$. Let $k_0 = (i, j)$, and let $\sigma = H_{<k_0} \cup \alpha_{k_0 - 1}$. By the definition of $\alpha_{k_0}$, it must be the case that $A^i = F_j^i(C)$ for all $C \supseteq \sigma$, otherwise $F_j^i$ would have been diagonalized against by $\alpha_{k_0}$ and would thus fail to reduce $A^i$ to $H$. Let $q_0$ be smallest such that $q_0 > i$ and $\sigma(\langle q', y \rangle)$ is undefined for all $y$ and $q' \geq q_0$. We will show that $d_{k;j}^i(q_0)$ succeeds on $H_n$ for some $n < q_0$, contradicting Fact 2 above.

For any $C \subseteq \mathbb{N}$ and $m \in \mathbb{N}$, we let $y_m$ and $E^C(m)$ be as before. For any $\ell$ and $y \geq y_{q_0}$ we have

$$\Pr C \left[ E^C(q_0 \ell) \mid \xi^H(q_0 \ell, y) \cap C \right] = 1$$
by the definition of $q_0$ and $y_{q_0\ell}$, and thus

$$\frac{\Pr_C[\mathbb{E}^C(q_0\ell) \mid \xi^H(q_0, y) \subseteq C]}{\Pr_C[\mathbb{E}^C(q_0\ell) \mid \xi^H(i, y) \subseteq C]} = \frac{\Pr_C[\mathbb{E}^C(q_0\ell) \mid \xi^H(i, y) \subseteq C]}{1} \geq 2^{-y_{q_0\ell}}$$

the last inequality following from Fact 1. From the definition of $d^{i,j}_{k,q_0;\ell}$, the following inequation can be shown for any $\ell$ and $y \geq y_{q_0\ell}$ (details are omitted)

$$\prod_{k=1}^{q_0-1} d^{i,j}_{k,q_0;\ell}(H_k[< y]) \geq 2^{-y_{q_0\ell}} \cdot \frac{\Pr_C[\mathbb{E}^C(q_0\ell) \mid \xi^H(q_0, y) \subseteq C]}{\Pr_C[\mathbb{E}^C(q_0\ell) \mid \xi^H(i, y) \subseteq C]}$$

Therefore,

$$\prod_{k=1}^{q_0-1} d^{i,j}_{k,q_0;\ell}(H_k[< y]) \geq 1$$

for all $y \geq y_{q_0}\ell$, which implies that $d^{i,j}_{k,q_0;\ell}(H_k[< y]) \geq 1$ for at least one $k$ between $i$ and $q_0 - 1$. Since $q_0$ is fixed and $\ell$ was chosen arbitrarily, by the Pigeon-Hole Principle there must be some $n_0$ with $i \leq n_0 < q_0$ such that for infinitely many $\ell$, $d^{i,j}_{n_0,q_0;\ell}(H_{n_0}[< y]) \geq 1$ for all $y \geq y_{q_0\ell}$. This in turn implies that the martingale $d^{i,j}_{n_0,q_0}$ succeeds on $H_{n_0}$, contradicting Fact 2.

Thus $A^i \neq F^j_i(H)$ for all $i$ and $j$, and Condition 3 is satisfied.

\[\square\] Theorem 12

**Corollary 14.** There is a sequence that is strongly deep but not strongly useful.

**Proof.** This follows immediately from Theorem 12 and the fact [6] that every weakly useful sequence is strongly deep.

It is easy to verify that weak and strong usefulness are both invariant under tt-equivalence. Thus, Theorem 12 shows that there are weakly useful tt-degrees that are not strongly useful. Our results do not say anything regarding the Turing degrees of weakly useful sets, however. In particular, we leave open the question of whether there is a weakly useful Turing degree that is not strongly useful (i.e., whether there is a weakly useful set not Turing equivalent to any strongly useful set). Some facts are known about these degrees. Jockusch [4] neatly characterized the strongly useful Turing degrees (under a different name), for example, as being either high or containing complete extensions of first-order Peano arithmetic. This includes some low degrees, but no non-high r.e. degrees. Recently, Stephan [14] has partially strengthened these results, showing that no non-high r.e. Turing degree can be weakly useful, either. Therefore, among the r.e. degrees, the strongly useful, weakly useful, and high degrees all coincide.
